Bias in research

Joanna Smith,¹ Helen Noble²

The aim of this article is to outline types of ‘bias’ across research designs, and consider strategies to minimise bias. Evidence-based nursing, defined as the “process by which evidence, nursing theory, and clinical expertise are critically evaluated and considered, in conjunction with patient involvement, to provide the delivery of optimum nursing care,”¹ is central to the continued development of the nursing professional. Implementing evidence into practice requires nurses to critically evaluate research, in particular assessing the rigour in which methods were undertaken and factors that may have biased findings.

What is bias in relation to research and why is understanding bias important?

Bias is defined by the Oxford Dictionary as: “an inclination or prejudice for or against one person or group, especially in a way considered to be unfair”; “a concentration on an interest in one particular area or subject”; “a systematic distortion of statistical results due to a factor not allowed for in their derivation” (http://www.oxforddictionaries.com). Understanding research bias is important for several reasons: first, bias exists in all research, across research designs and is difficult to eliminate; second, bias can occur at each stage of the research process; third, bias impacts on the validity and reliability of study findings and misinterpretation of data can have important consequences for practice. The controversial study that suggested a link between the measles-mumps-rubella vaccine and autism in children⁵ resulted in a rare retraction of the published study because of media reports that highlighted significant bias in the research process.⁶ Bias occurred on several levels: the process of selecting participants was misrepresented; the sample size was too small to infer any firm conclusion from the data analysis and the results were overstated which suggested caution against widespread vaccination and an urgent need for further research. However, in the time between the original publication, and later research refuting the original findings, the uptake of measles-mumps-rubella vaccine in Britain declined, resulting in a 25-fold increase in measles in the 10-year period following the original publication.

Although different study designs have specific methodological challenges and constraints, bias can occur at each stage of the research process (table 1). In quantitative studies having a well-designed protocol explicitly outlining data collection and analysis can assist in reducing bias. Feasibility studies are often undertaken to refine protocols and procedures. Bias can be reduced by maximising follow-up and where appropriate in randomised control trials analysis should be based on the intention-to-treat principle, a strategy that assesses clinical effectiveness because not everyone complies with treatment and the treatment people receive may be changed according to how they respond. Qualitative research has been criticised for lacking transparency in relation to the analytical processes employed.⁷ Qualitative researchers must demonstrate rigour, associated with openness, relevance to practice and congruence of the methodological approach. Although other researchers may interpret the data differently, appreciating and understanding how the themes were developed is an essential part of demonstrating the robustness of the findings. Reducing bias can include respondent validation, constant comparisons across participant accounts, representing deviant cases and outliers, prolonged involvement or persistent
Table 1 Types of research bias

<table>
<thead>
<tr>
<th>Bias Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Design bias</td>
<td>Poor study design and incongruence between aims and methods increases the likelihood of bias. For example, exploring HIV testing using a survey is unlikely to obtain in-depth rich data about individuals’ experiences. Bias can occur when a researcher’s personal beliefs influence the choice of research question and methodology. For example, a researcher working for a pharmaceutical company may choose a research question which supports the usefulness of the drug being investigated.</td>
</tr>
<tr>
<td>Selection/participant bias</td>
<td>Selection bias relates to both the process of recruiting participants and study inclusion criteria. Successful research begins with recruiting participants who meet the study aims. For example, recruitment bias could occur if participants were invited to participate in a survey posted on the internet, which automatically excludes individuals without internet access. Inclusion bias in quantitative research typically relates to selecting participants who are representative of the study population, and where applicable allocation of participants to ensure similarity between comparison groups. In addition, accounting for the differences between people who remain in a study and those who withdraw may be important in some study designs. For example, an evaluation of a weight loss programme may be affected by participant withdrawal; participants who become disillusioned because of not losing weight may drop out, which may bias the findings towards more favourable results. Confounding bias can also occur because of an association between ‘cause’ and ‘effect’. For example, comparing treatment outcomes for similar conditions between general and specialised centres may find higher mortality rates at specialised centres yet patients referred to these centres are more likely to have high-risk factors and more complex needs. In qualitative research, it is usual to recruit participants with a range of experiences in relation to the topic being explored; therefore, accounting for biases in relation to the sampling strategies is essential. For example, recruiting parents from a parent and toddler group is likely to be biased towards mothers; the findings are unlikely to represent both mothers’ and fathers’ perspectives.</td>
</tr>
<tr>
<td>Data collection bias and measurement bias</td>
<td>Data collection bias can occur when a researcher’s personal beliefs influence the way information or data is collected. In quantitative studies, measurement bias can occur if a tool or instrument: has not be assessed for its validity or reliability (e.g., using a shared decision-making tool that measures patient satisfaction rather than decision-making); is not suitable for the specific setting or patient groups (e.g., using an adult verbal pain assessment tool with young children); an instrument not calibrated properly may consistently measure inaccurately (e.g., weighing babies with poorly calibrated weighing scales). In retrospective studies, for example, when completing questionnaires about eating habits when data collection relies on recall, participants may not remember and report events accurately. In qualitative research, interviewing is a commonly used method of data collection; how questions are asked will influence the information elicited. For example a leading question, “Do you find the health service poor?”, is likely to receive a closed yes or no response, and not gain insight into participants experiences and could be replaced with; “Please describe your last visit to hospital!”</td>
</tr>
<tr>
<td>Analysis bias</td>
<td>When analysing data, the researcher may naturally look for data that confirm their hypotheses or confirm personal experience, overlooking data inconsistent with personal beliefs.</td>
</tr>
<tr>
<td>Publication bias</td>
<td>Published studies nearly always have some degree of bias. For example, in quantitative research, studies are more likely to be published if reporting statistically significant findings. Non-publication in qualitative studies is more likely to occur because of a lack of depth when describing study methodologies and findings are not clearly presented.</td>

observation of participants, independent analysis of the data by other researchers and triangulation.3

In summary, minimising bias is a key consideration when designing and undertaking research. Researchers have an ethical duty to outline the limitations of studies and account for potential sources of bias. This will enable health professionals and policymakers to evaluate and scrutinise study findings, and consider these when applying findings to practice or policy.
