Review: some preschool children develop complications after presenting to primary care with acute cough

**QUESTION:** In children 0–4 years of age presenting to primary care with the symptom of acute cough or an undifferentiated acute respiratory tract infection with cough (UARTIC), what is the natural history of illness duration and complications?

**Data sources**
Studies were identified by searching Medline (1966 to September 1998), EMBASE/Excerpta Medica (1988 to September 1998), the Cochrane Library databases, Bandolier, and the *Drug and Therapeutics Bulletin* using the content terms respiratory tract infection (RTI), cough, bronchitis, and chest infection; and by reviewing references of relevant articles.

**Study selection**
Studies published in English were selected if they were cohort studies, control or placebo arms of randomised controlled trials (RCTs), systematic reviews of RCTs, and if patients were preschool children 0–4 years of age presenting to primary care with acute cough. For study selection, the review used the symptom of cough or UARTIC defined as a cough that failed to differentiate into a recognised clinical picture with known associated bacterial or viral aetiology, such as croup, whooping cough, pneumonia, or bronchiolitis. UARTIC included conditions labelled upper RTI, bronchitis, chest infection, and postnasal drip. Studies examining non-UARTIC, including pertussis and persistent wheezing, were excluded, as were those where a primary care physician was not consulted or the research was based in developing countries.

**Data extraction**
1 author screened >6000 titles online and the grey literature, scrutinised 40% of these, and excluded 384. 2 authors independently assessed 21 studies for relevance and excluded 11. Each then independently extracted data on study characteristics, patient demographics, patient inclusion and exclusion criteria, recruitment and follow up rates, duration of follow up, and outcomes for the remaining 10 studies. The main outcomes were duration of illness and complications.

**Main results**
2 cohort studies and 8 RCTs met the selection criteria. 65% of all children (where age data were given) were 0–4 years of age. At 1 week after consultation, most children (86% and 75%) in 2 studies (illness duration measured by parent completed symptom diaries), 51% in 1 study (illness duration measured by physician assessment as ‘recovered’), and only 8% in another study (illness duration measured by parent completed diaries) had improved; but about half were still coughing (49% in 1 study) and/or had nasal discharge (55% in 2 studies). At 2 weeks, up to 24% of children in 1 study had not ‘recovered’ or were worse (physician assessment), and up to 66% still had symptoms in another study (illness duration measured by parent completed diaries). Meta-analysis of 6 studies (n=1777) showed that 12% (95% CI 11% to 14%) of children had ≥1 complication, such as rash, painful ears, diarrhoea, vomiting, or progression to bronchitis/pneumonia within 2 weeks of presentation.

**Conclusion**
In children 0–4 years of age who presented to primary care with acute cough, 24% of children in 1 study were judged by the physician to not have recovered or to be worse 2 weeks after the initial consultation. Meta-analysis of 6 studies showed that 12% developed ≥1 complication, such as rash, painful ears, or bronchitis/pneumonia.

**COMMENTARY**
In this review, Hay and Wilson have tackled the difficult job of collecting data on acute cough illness in children from several studies. However, 2 limitations of the studies in the review deserve particular note. (1) The paucity of physician data on illness duration at first consultation in these studies threatens the validity of the conclusions about the duration of symptoms. If the 1 study that did collect this information is any indicator, illness duration at first visit varies widely, making calculation of total duration questionable. (2) The study by Gulbrandsen et al., 49% and 24% of children were unwell at <4 days and at >2 weeks, respectively. The initiator of repeat consultations (parent or physician) varied between the studies. The criteria for judging improvement, resolution, or duration of symptoms are likely to be different for each of these 2 groups.

Respiratory tract infections (RTIs) are a major cause of morbidity in young children. Paediatricians and family physicians report that RTIs account for >10% of their office visits. The cost is large in terms of lost parental work time. The lack of good prognostic information is a major stumbling block to the campaign to reduce antibiotic use in respiratory illnesses. The conclusions of Hay and Wilson confirm what many practitioners know about UARTIC: the best indication that treatment is needed is probably the prolonged duration of symptoms. Experienced practitioners know that some children will develop complications. In the case of persistent cough, persistence of symptoms could be caused by bronchiolar hyperreactivity, persistent postnasal drip, or secondary bacterial invasion.

A reliable history of past illnesses or personal experience of the child who presents with UARTIC symptoms may predict complications at onset, but evidence is lacking. This review provides the only available summary data about duration of symptoms and percentages of complications in acute cough. It assists practitioners in providing information and advice to parents and suggests that a “wait and see” approach may be the only sensible first line treatment.
