Fluoxetine plus cognitive behavioural therapy was most effective for adolescents with major depressive disorder

Q In adolescents with major depressive disorder (MDD), how do fluoxetine, cognitive behavioural therapy (CBT), and their combination compare for effectiveness?

METHODS

Design: randomised controlled trial (RCT).
Allocation: (concealed).*
Blinding: blinded (patients and healthcare providers [fluoxetine v placebo comparison], and outcome assessors).
Follow up period: 12 weeks.
Setting: outpatient clinic in the US.

Patients: 439 adolescents (mean age 15.1 y, 54% girls) who had a DSM-IV diagnosis of MDD, could attend an outpatient clinic, scored >45 on the Children’s Depression Rating Scale–Revised (CDRS–R), had a full scale IQ >80, and were not taking antidepressants. Exclusion criteria included bipolar disorder, severe conduct disorder, substance abuse/dependence, 2 failed selective serotonin reuptake inhibitor (SSRI) trials, and poor response to CBT.

Intervention: fluoxetine, from 10 mg/day to a maximum of 40 mg/day by week 8 (n = 109); CBT (n = 111); CBT plus fluoxetine (n = 107); or placebo (n = 112). CBT consisted of 15 sessions (50–60 min each) for 12 weeks and aimed to correct depressive thought patterns and increase positive reinforcing behaviour patterns.

Outcomes: CDRS–R score (range 17–133; high scores = greater depression), Suicidal Ideation Questionnaire–Junior High School Version score, and Clinical Global Impressions–Improvement (CGI–I) response rate (much improved or very much improved).

Patient follow up: 82% (100% included in intention to treat analysis).

*Information provided by author.

MAIN RESULTS

Fluoxetine plus CBT led to greater improvement in CDRS–R scores than placebo (mean difference 7.6, *p = 0.001), fluoxetine (mean difference 4.4, *p = 0.02), or CBT (mean difference 9.4, *p = 0.001). Fluoxetine plus CBT also reduced suicidal thoughts.

Fluoxetine plus CBT and fluoxetine had greater CGI–I response rates relative to placebo and CBT alone. Numbers needed to treat were 3 (95% CI 2 to 4) for fluoxetine plus CBT and 4 (CI 3 to 8) for fluoxetine alone relative to placebo. The 2 fluoxetine groups had more harm related events than the CBT alone and placebo groups (table).

CONCLUSION

In adolescents with major depressive disorder, fluoxetine plus cognitive behavioural therapy was most effective.

Commentary

Few well designed studies have assessed treatments for MDD in adolescents. A recent public health advisory from the US Food and Drug Administration (FDA) questioned the safety of SSRIs because of increased suicidal behaviours in adolescents and children. In the UK, the regulator has strongly advised against the use of all SSRIs except fluoxetine in adolescents and children (http://www.mhra.gov.uk/news/sri_101203.htm accessed 13 Jan 2005).

TADS offers some strong support for 12 weeks of fluoxetine plus CBT. Study strengths are the RCT design, double blind in the fluoxetine and placebo groups, the inclusion of adolescents with comorbidities, and the data safety and monitoring protocol conducted by the National Institute of Mental Health.

Patients in the CBT plus fluoxetine and CBT alone groups were not blinded, which might have affected the findings if these patients expected improved outcomes. Adolescents with substance abuse, recent suicide attempts, or suicidal ideation were excluded; thus findings are not generalisable to all adolescents with MDD. Some of these adolescents are most in need of treatment. A study weakness was the exclusion of non-English speaking adolescents or parents. The modal income reflected a high middle class, thus missing many adolescents with lower socio-economic status who have MDD. The study report did not describe how the fidelity of the CBT intervention was monitored. The treatment duration of 12 weeks does not offer support for longer use of either treatment.

TADS provides evidence that fluoxetine plus CBT is effective for adolescents with MDD, including those with some comorbid conditions. However, the advisory from the FDA should also be considered. Antidepressant medications may increase the risk of suicidality or other harm related adverse events. Nurses must continue to monitor depressed adolescents for suicidal thinking and behaviour. This includes providing anticipatory guidance to parents or guardians about signs to observe and actions to take. Further study is needed to determine the longer term effects of combined pharmacological and psychotherapeutic treatments for the wide array of adolescents who have MDD.
